Abstract

The electronic transmission properties of DNA molecules are believed to play a significant role in many physical phenomena taking place in living organisms [1]. Here we study the charge transport (CT) properties of cancer-related genes, including some of the most important tumor suppressors. We find that the changes in averaged CT around the sites of pathogenic and cancerous mutations are statistically smaller than those on sites where pathogenic mutations have not been observed. The results suggested that CT might be an indicator to discriminate between pathogenic and non-pathogenic mutations at an early stage. Mutations which cause little change in CT may be more likely to occur, or more likely to be missed by damage-repair enzymes which probe CT, and are therefore more likely to persist and cause disease.

Keywords: deoxyribonucleicacid, charge transport, cancer, mutation

Revision : 1.28

We study the relation between the point mutations and CT properties of some of the most important tumor suppressors, together with other cancer-associated genes. These genes regulate cell proliferation by monitoring various molecular signaling pathways. Disfunction of the tumor suppressors will cause abnormal cell proliferation and the development of cancers [2]. CT through DNA is inhibited at the damaged sites of the sequence, owing to misalignments of base pair π -stacking [1]. The base excision repair (BER) enzymes such as Endonuclease III and MutY are believed to efficiently locate the DNA base lesions or mismatches by probing the inhibition of the DNA-mediated CT due to the damages [3].

We have previously studied [4] the CT properties of the genomic sequence of the *p53* tumor suppressor gene, which is known as the “guardian of the genome”. The results show that on average the cancerous mutations of the gene yield smaller changes of the CT in contrast with non-

cancerous mutations. Based on such a behavior of CT, we proposed a possible scenario of how cancerous mutations might circumvent the DNA damage-repair mechanism and survive to yield carcinogenesis [4]. Here we will add to this analysis by showing that the *p53* gene with a randomly rearranged sequence does not show this effect at all. This test has also been applied to many other genetic sequences.

The native genetic sequences and mutations of cancer-related genes are retrieved from four different databases [5, 6]. The genomic sequence of a gene with length \mathcal{N} base pairs (bps) is defined as $(s_1, s_2, \dots, s_{\mathcal{N}})$. Each point mutation of a given gene is characterized by the set (k, s) , where k and s are the position of the point mutation in the genomic sequence and the mutant nucleotide which replaces the nucleotide s_k of normal DNA, respectively.

The simplest model of coherent hole transport in DNA is given by an effective one-dimensional

Figure 2: Distribution of the change in charge transport Γ for pathogenic (white bars) and all possible (grey bars) mutations for the $p53$ DNA strand with 20304 base pairs. The left/right columns show results for the 1D/diagonal models while the top/bottom rows indicate original/shuffled DNA sequences. For the randomly shuffled cases, error bars are calculated using 20 different sequence realizations. All results are for $L = 40$. The line for the 1-D case is a fit to a log-normal distribution.

Those k with more than one pathogenic mutations are excluded in the LR analysis. Similarly, we define a *global ranking* (GR) by ranking the normalized CT changes for *all possible* $3N$ mutations. We assign global ranks $\gamma_{GR}(k, s; L)$ of 1 for the lowest third of the global distribution of CT changes, 2 for the middle third and 3 for the top third. In Fig. 3 we show the incidences of the three possible local and global ranks for the cancerous mutations of $p53$. In local rankings, the incidence of pathogenic mutations with lowest CT change, $\gamma_{LR} = 1$, is significantly higher than for $\gamma_{LR} = 2, 3$. However, this result is barely distinguishable from the distributions of local rankings for shuffled sequences. In the global ranking, however, the incidence of pathogenic mutations with $\gamma_{GR} = 1$ is higher than for $\gamma_{GR} = 2, 3$ and the distribution for the native sequence *is* distinguishable from the distributions for shuffled sequences.

In total, we have performed these statistical tests for 35 cancer DNA sequences [5, 6]. The results [10] show that in about 95% of the DNA strands the pathogenic mutations are biased towards smaller changes in CT properties. Hence it seems very likely the scenario proposed here for early pathogenesis can be applied for an analysis

Figure 3: Distribution of the *local*, LR (top row) and *global*, GR (bottom row) ranking results of pathogenic mutations of $p53$ (open symbols) as a function of window lengths L . Circles indicate the proportion of pathogenic mutations with $\gamma = 1$; squares, $\gamma = 2$; diamonds, $\gamma = 3$. The closed symbols indicate averaged results for 20 randomly shuffled sequences. The left/right columns distinguish results for the 1D/diagonal models. The dotted horizontal lines show the 33% mark expected for a uniform random distribution.

of a wide range of genetic diseases.
